THE UNCONTAINED CONDITION

War, Nuclear Systems, and the Failure of Permission

By Sum Bunny 2026

I. The Category Error Nuclear systems are among the most carefully engineered structures in human history. They are designed to fail—not perfectly, but predictably. They assume internal failure: valves will stick, operators will misread, and power will fail. Modern nuclear engineering is the achievement of making these failures **internal** to the system.

But there is a category error embedded in this success. These systems are designed for failure inside the system. They are not designed for **prolonged, adversarial degradation of externalized dependencies combined with sustained loss of coordination capacity.**

II. The Earned Condition In high-reliability engineering, creation is conditional. You do not build the reactor core until you have built the containment vessel. This is not "best practice"; it is **Structural Permission**.

The Law of Safe Generativity: A system is only entitled to produce the level of complexity for which it has already established the capacity to safely manage failure.

A system earns the right to operate by demonstrating that it can survive its own collapse.

III. Externalized Dependencies Every system rests on conditions it does not build. Nuclear safety models assume a stable power grid, intact logistics, and coordinated emergency response. These are not engineered features; they are **Externalized Dependencies**. They are required for safety but are not controlled by the system itself.

IV. Blind Spots Have Mass A blind spot is the necessary shadow of a system that works. Nuclear safety models treat external hazards as **bounded events** rather than sustained conditions that degrade the system's ability to respond over time. When "Peace" is removed as a background constant, the shadow of these unmodeled conditions acquires mass and exerts force back on the system.

V. The Constraint All systems of persistence operate under a fundamental boundary condition:

$$D \leq R$$

Where **D (Generative Flux)** represents energy and entropy production, and **R (Absorptive Capacity)** represents containment and response bandwidth. These terms are structural mappings across domains where energy, information, and coordination must be balanced.

The transition from $D \leq R$ to $D > R$ is empirically indicated by the **loss of stable feedback, delayed correction, and irreversible state transitions** within system-relevant timescales. If D >

R, the system undergoes **nonlinear reorganization**—it breaks the existing structure to find a new, uncontained equilibrium.

VI. Decay Heat: The Irreducible D Unlike a gas plant, a nuclear reactor cannot be "turned off" in the physical sense. Even after fission stops, **Decay Heat** continues. This heat does not respond to damage, disruption, or intent. It continues regardless of system state. In the unmodeled condition, D persists independent of the capacity to manage it.

VII. War as Dual Constraint Violation War is one instance of a broader class: **adversarial or destabilizing inputs that degrade system coordination while increasing generative stress.** In such states, infrastructure decays under adversarial acceleration, acting as a dual-force multiplier:

1. **D Rises:** Emergency operations and unstable conditions increase system stress.
2. **R Falls:** The collapse of coordination and infrastructure destroys the capacity to manage the flux.

More precisely:

$dD/dt > dR/dt$

The rates are defined relative to system-relevant timescales of coordination and response. The rate of chaos outpaces the rate of control.

VIII. Robustness vs. Resilience Nuclear systems are **Robust**, not **Resilient**.

- **Robust systems** are designed to resist failure from modeled, discrete shocks.
- **Resilient systems** are designed to survive and adapt after failure occurs.

War converts robustness into brittleness. When coordination bandwidth collapses, feedback loops degrade, and corrective signals arrive too late to stabilize the system.

IX. Ontological Outlawry Permission is not legal; it is structural. **Ontological Outlawry** is the condition where a system persists despite violating its own constraint boundary ($D > R$). When a system crosses this line, the conditions that justified its structural permission no longer obtain.

Operating a nuclear plant in a theater of war is a state of **Unearned Continuation**—the system continues to produce complexity under conditions for which containment was never demonstrated.

X. The Human as Complexity Sink When R collapses, the load does not vanish; it moves. If the system cannot absorb its own failure, the environment must. The human becomes the **Complexity Sink**, forced to process the energy and informational load that the engineering could not. This is not moral failure; it is **Constraint Overflow**.

XI. The Observer Paradox The system loses the capacity to accurately model its own state while the conditions needed for that modeling are themselves degrading. This is a terminal form

of recursive collapse: an observer tracking their own dissolution while the tools of observation are being consumed by the void. As the lyric suggests, it is the condition of watching oneself "crawlin' out as I was a-crawlin' in."

XII. Conclusion: The Condition This framework is a **constraint diagnosis** for any system built for stability operating within environments that are no longer stable. Nuclear systems are one instance of this condition, not its limit; the condition is recursive, emerging in any system that depends on externalized constants for its internal safety.

When those constants collapse, safety does not degrade.

It disappears.
